## **Abstract**

1  
2 This paper presents a firsthand comparative evaluation of three different existing methods  
3  
4 for selecting a suitable allograft from a bone storage bank. The three examined methods are  
5  
6 manual selection, automatic volume-based registration, and automatic surface-based  
7  
8 registration. Although the methods were originally published for different bones, they were  
9  
10 adapted to be systematically applied on the same data set of hemi-pelvises. A thorough  
11  
12 experiment was designed and applied in order to highlight the advantages and disadvantages  
13  
14 of each method. The methods were applied on the whole pelvis and on smaller fragments,  
15  
16 thus producing a realistic set of clinical scenarios. Clinically relevant criteria are used for the  
17  
18 assessment such as surface distances and the quality of the junctions between the donor and  
19  
20 the receptor. The obtained results showed that both automatic methods outperform the  
21  
22 manual counterpart. Additional advantages of the surface-based method are in the lower  
23  
24 computational time requirements and the greater contact surfaces where the donor meets the  
25  
26 recipient.

## Introduction

1  
2 Bone allograft reconstruction is an accepted procedure for the recovery of the original  
3 anatomy following a pathological or traumatic defect. Biological and prosthetic implants are  
4 among the various existing reconstruction methods. The choice of treatment is mostly a case-  
5 specific decision.<sup>1</sup> Despite their high complication rate and their slow incorporation into the  
6 host bed, biological massive allografts are recommended for great defects such as traumatic  
7 or pathological defects of the pelvis. Clinical reports suggest that this approach preserves the  
8 long-term bone stock and limb functionality.<sup>1,2,3,4,5,6,7</sup> Furthermore, long-term follow-up  
9 studies support and promote the use of allografts instead of prosthetic implants especially in  
10 younger patients.<sup>2,5</sup>

23  
24  
25  
26  
27 A poor anatomical matching between the host and the donor can alter the joint kinematics  
28 and load distribution, leading to articular fractures or joint degeneration.<sup>3,8</sup> Therefore, size  
29 and shape determination is critical to obtain an appropriate allograft.<sup>9</sup> Moreover, optimal  
30 handling of the bone bank ensures minimal loss of the usually scarce cadaver bone stock.

31  
32  
33  
34  
35  
36  
37  
38  
39 Access to bone allografts was facilitated with the development of centralized bone banks  
40 where bones are collected from cadavers, fresh-frozen for storage, and distributed to medical  
41 centres.<sup>10</sup> The bank systems sometime digitally store three-dimensional copies of the bones  
42 and use them for the selection process. However, the task of selecting a suitable allograft  
43 remains a major challenge.<sup>11</sup> Typically, bone banks select an appropriate donor by manually  
44 measuring anatomical dimensions on 2D radiographs.<sup>14</sup> Such a manual approach is rather  
45 subjective, time-consuming, and prone to errors. This calls for the need to introduce  
46 automated and more accurate techniques for this specific task. Figure 1a illustrates the major  
47 functions of a bone banking facility in which donors are scanned and reconstructed in 3D.<sup>9</sup>

1  
2 This work is a joint collaboration between the authors of three allograft selection methods  
3  
4 aiming to provide a comprehensive comparison and evaluation of their respective  
5  
6 performance and reliability. Although the methods were originally published for different  
7  
8 bones, they were adapted to be systematically applied on the same data set of hemi-pelvises.  
9  
10 The overall experimental design is illustrated in Figure 2. The paper starts by briefly  
11  
12 reintroducing the methods. The evaluation protocol is then described. The results and  
13  
14 statistical analysis are subsequently listed and discussed.

## 31 **Materials and Methods**

### 32 *Evaluated Allograft Selection Methods*

33  
34 Recent efforts aimed at developing methods capable of reliably selecting a bone fragment  
35  
36 that matches the resection-specific anatomy of the patient. Of interest to this work are three  
37  
38 conceptually different methods that share the same purpose. The first allograft selection  
39  
40 method is mostly manual but uses a computerized virtual environment.<sup>9</sup> The second bases the  
41  
42 search on image-to-image – or volume – registration.<sup>12</sup> Whereas, the third method utilizes  
43  
44 surface-to-surface registration.<sup>13</sup>  
45  
46  
47  
48  
49  
50

51  
52 All three methods share the same objective, that is to find among a set of healthy bones  
53  
54 (hereafter designated as donors), the fragment(s) that closely resemble(s) the morphology of  
55  
56 the bone to be reconstructed (hereafter designated as recipient). The methods also delineate  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 the bone regions where the donor bone has to be cut to assist with the extraction of the  
2 allograft. The following paragraphs offer a brief description of the three methods under  
3 scrutiny.  
4  
5

6  
7  
8  
9 *Manual Selection-* Manual selection based on 2D template comparison is the current gold  
10 standard for selecting an appropriate allograft.<sup>14</sup> A more advanced method for manual  
11 selection based on a 3D reconstruction of CT images of the available donors was proposed by  
12 Ritacco *et al.*<sup>9</sup> The computer tools and virtual environment used might vary, but the approach  
13 is unchanged. The user interacts with the virtual models and tries to adequately position and  
14 align the recipient to all donors in the bank. A subsequent visual assessment is carried out to  
15 select the most appropriate donor(s). The computer system used for this purpose consists of a  
16 dual core 2.00 GHz processor with 2GB of RAM, running under Windows<sup>®</sup> XP. In Ritacco *et*  
17 *al.*,<sup>9</sup> the authors augment the morphological information by adding three anatomical distances  
18 measured between manually placed landmark points. Figure 1c shows the landmark  
19 configuration system used in Ritacco *et al.*<sup>9</sup>

34  
35  
36  
37  
38

39 *Volume-Based Registration-* Volume-based or image-to-image registration was used in this  
40 method<sup>12</sup> to match similar objects (recipient and donor). Only rigid registration was applied in  
41 order to preserve the morphology of the bones. A similarity metric composed of intensity-  
42 based difference between voxels of two images is computed and used for the optimisation of  
43 the registration. Surface-to-surface distance was used to rank the donors and as a selection  
44 criterion. A 64-bit 8-core Intel<sup>®</sup> i7 1.60 GHz with 8 GB of RAM running under Windows<sup>®</sup> 7  
45 was used for the application of this method. Figure 3 illustrates how the rigid registration  
46 algorithm transforms one image to fit another. The authors concluded that this method is  
47 faster and more reliable than the gold standard method that they used in their previous  
48

2 manually aligned with radiographs of the donors.  
3  
4

5  
6  
7 HERE GOES FIGURE 3  
8  
9

10  
11  
12 *Surface-Based Registration-* This method<sup>13</sup> is directly applied on surface representations of  
13 the bones of interest. The surfaces are composed of a dense set of points generated by  
14 segmenting CT (computed tomography) images and 3D reconstructing the individual bones  
15 (Figure 1b). An ICP-based (iterative closest point<sup>15</sup>) algorithm is applied in order to compute  
16 the transformation that results in the best fit between the recipient and a donor bone. The  
17 process is repeated until the recipient is registered to all bones in the database. Surface  
18 distance metrics are then used to select the best matching allograft(s). A 32-bit architecture,  
19 3.00 GHz Intel<sup>®</sup> Core<sup>™</sup> 2 Duo CPU with 3.25 GB of RAM was used for the automatic  
20 selection method. The allograft sorting and selection metric is the same used for the volume-  
21 based method. Figure 4 shows an example from the original work showing a sample result of  
22 the surface-based registration method applied on the distal femur. Surface distances are  
23 illustrated in the form of color maps for the best two and worst donors. The authors reported a  
24 significant improvement over the manual method in terms reliability and repeatability while  
25 keeping a good agreement with the gold standard. For the particular bones, the reported  
26 computation time is also considerably lower than that of the manual selection<sup>9</sup> and volume  
27 registration.<sup>12</sup> However, the study<sup>13</sup> was not meant as a comprehensive evaluation and the  
28 dataset used for the evaluation was not consistent among the different methods.

## Experimental Data

As mentioned in the previous section, and in order to present an unbiased evaluation and comparison, the three methods were applied on the same dataset. The dataset consists of ten left hemi-pelvises extracted from CT images of cadaveric specimens (1.0mm slice spacing, 2.7mm slice thickness, 1.0 second per 360° rotation, peak 90 kV). Each segmented hemi-pelvis was reconstructed to obtain a three-dimensional point cloud (Figure 1b). The points were triangulated to form a surface mesh of each instance for enhanced visualisation. This dataset is considered as the common ground data to be treated as donors by all three methods. An experienced surgeon applied cuts on each one of the ten hemi-pelvises in order to divide them into three separate fragments. The fragments correspond to common clinical scenarios of resection and grafting and consistent with the guidelines presented in Enneking *et al.*<sup>16</sup> The three fragments are assigned the letters A, B, and C for the iliac, acetabular, and pubic regions, respectively. The cuts are carried out using virtual planes in a 3D environment. This resulted in a total of four categories, each made of ten recipients. The first is the data set with the intact hemi-pelvis. The other three are composed of either one of the three cut out fragments. Figure 5 shows one example of the cutting configuration and the resulting junctions. A junction is defined as the contact surface between the recipient and the corresponding potential donor. In the current configuration, fragment A has one junction, whereas fragments B and C have three and two junctions, respectively. Fragments A and C are slightly less realistic as the sacroiliac and the pubic joints are not included in our analysis. However, slight relative motion is allowed at the level of these joints, a smooth and rigid transition is not as crucial as it is at the level of bone-to-bone junctions.

HERE GOES FIGURE 5

## *Testing Protocol*

1  
2 The three allograft selection methods, namely manual selection, volume-based registration,  
3 and surface-based registration were applied on the datasets described earlier. An experiment  
4 is defined as the registration of every recipient to all donors in the databank and the  
5 subsequent sorting of donors in descending order of similarity to each recipient. Having four  
6 categories of recipients and one category of donors, four registration experiments were  
7 performed by each method. The first experiment considers the intact hemi-pelvis as a  
8 recipient, whereas the other three experiments use the individual fragments as recipients.  
9  
10  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21

22 In all experiments, the databank of donors is composed of the set of intact hemi-pelvises. The  
23 measure of similarity is a method-specific quantity. The direction of the registration  
24 (definition of fixed and moving entities) also depends on the method being applied. However  
25 the results reported herein are rearranged for consistency. In total,  $10 \times 10$  (= 100) individual  
26 registrations are carried out for every experiment.  
27  
28  
29  
30  
31  
32  
33  
34  
35

36 Since the recipients are extracted from the same set of donors, there will be one registration  
37 per recipient that is expected to result in a virtually perfect overlap. This hemi-pelvis will be  
38 referred to as a trap graft and was also included in the experiments. A random spatial  
39 transform (translation and rotation) was applied to all donors prior to starting the process in  
40 order to eliminate subjective biases caused by already overlapping trap grafts. The datasets  
41 were then stored under modified file names for complete experimental blindness.  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52

53 Following each registration process, we used the initial cutting planes used to separate the  
54 individual fragments to extract the interfaces between the donor and recipient. For every  
55 junction, the surface area of the junctions from either side, as well as that of their intersection,  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 was computed. Dice coefficients<sup>17</sup> quantifying the quality of the contact surfaces at the  
2 interface between the donor and the recipient were calculated. Dice coefficients can take  
3 values within the range [0, 1], and describe the amount of overlap between two areas. Figure  
4 6 shows an example of overlapping contact surfaces at the junction area.  
5  
6  
7  
8  
9

10  
11 We also computed surface distance metrics between the donors and the recipients. The mean  
12 surface distance consists of the average value of the individual Euclidean distances between  
13 corresponding surface points (generated using a space dividing *kd*-tree). It provides  
14 information about the overall global similarity between the two surfaces. The Hausdorff  
15 surface distance<sup>18</sup> is the largest amongst the individual Euclidean distances and it indicates  
16 the largest possible distance between the two surfaces.

### 34 *Comparative Evaluation and Statistical Analysis*

35

36 In order to present a comprehensive evaluation and comparison of the methods, a set of  
37 statistical tests was designed and applied on the final outcome of the methods.<sup>19</sup> The first test  
38 is aimed to compare the ability of the different methods to correctly detect and classify the  
39 trap graft. For this purpose, Fisher's exact test was applied to check for differences between  
40 the various outcomes. The Chi-squared test was not used because some of the expected  
41 frequencies in the contingency tables were smaller than 5. A significance level of 0.05 was  
42 chosen for this and all subsequent tests.  
43

determined by calculating the corresponding Cohen's kappa.<sup>20</sup> The levels of agreement are classified according to the standard interpretation of Cohen's kappa.<sup>21</sup>

In order to measure the statistical significance of the differences between different corresponding measurements, methods using analysis of variance or ANOVA were applied. Except for the processing time, the evaluation measurements were applied exclusively on the three best ranked candidate donors by each of the methods. The processing time indicates the time required by the manual or automatic selection only, without taking into account the time needed to load and unload the data from the system's memory.

## Results

In most cases, all methods were successfully able to detect the trap graft. Only for the case of fragment A (FA), the manual method failed to detect the trap graft four out of ten times. Fisher's exact test resulted in an overall *p*-value of 0.116, indicating a difference that is not statistically significant between the groups and therefore all three methods were able to detect the trap graft with similar performance.

HERE GOES TABLE 1

Cohen's kappa was used to assess the level of agreement of the three methods in selecting the best three candidate donors and the corresponding results are listed in Table 1. There is a general agreement between the different methods with varying levels. We did not record any cases where a clear disagreement or accidental agreement in the selection was obtained.

HERE GOES FIGURE 7

1  
2 In terms of time requirement, the manual and the volume registration methods required  
3  
4 approximately the same amount of time without evidence of significant difference. However,  
5  
6 the manual method requires continuous user input, whereas the volume-based method can be  
7  
8 ran as a background process. The surface-based method performed substantially faster. The  
9  
10 average time for a single registration required by each of the methods is compared and  
11  
12 illustrated in Figure 7. Both automatic methods have an overhead time of loading and  
13  
14 unloading the data into memory which was not included in the analysis. However, this time  
15  
16 depends on the specific hardware being used and the type of data (images or surface  
17  
18 representations).

Figure 8 shows a comparison of the resulting surface distances, namely, the mean and the Hausdorff surface distances, between the donors and the recipients.. For all cases, the manual method resulted in higher surface-to-surface distances and both automatic methods yielded statistically significant improvement. However, mostly not significant differences are measured between the results of the two automatic algorithms, with the exception of the Hausdorff distance at fragment A.

Of high interest to the outcome of the intervention is the quality of the contact surface overlap at the level of the junctions between the donor and the recipient bones. The corresponding measurements are shown in Figure 9 for all junctions described in Figure 5. Interestingly, in most cases the automatic methods outperform the manual counterpart, and the surface-based method is often yielding the best overlap. Moreover, statistically significant differences

1 between the qualities of the overlap were obtained in two cases, in particular at junction 1 of  
2 fragment B and junction 1 of fragment C.

## 10 11 12 13 14 **Discussion** 15

16  
17 In this paper we presented a comparative evaluation of the performance of three different  
18 allograft selection methods. One manual and two automatic methods were the subject of this  
19 study. We used the pelvis as a target site due to its complex morphology, prevalence (around  
20 30 malignant pelvis tumors per year in Argentina, 75 massive bone allografts per year in  
21 Belgium out of which 15 of the pelvis) of the procedure, and the difficulty of bone grafting in  
22 this specific location. Several criteria were used for the assessment. In particular, the ability  
23 of the methods to detect the trap grafts, the agreement between the methods over the selection  
24 and ranking of candidate donors, surface-to-surface distances between the donor and the  
25 recipient, quality of the overlap at junction levels, and required processing time. Input data  
26 was standardized for all three methods and subjective bias was eliminated.

44 The obtained results clearly indicated that both automatic methods outperformed the manual  
45 selection in all measured aspects while maintaining the agreement about the best three ranked  
46 donors. In contrast to the standard 2D template search,<sup>14</sup> all methods were able to accurately  
47 detect the trap graft with exceptions that are not statistically significant. This finding indicates  
48 that the manual method based on comparison of 3D models performs better than the manual  
49 method based on 2D templates,<sup>14</sup> which failed in consistently detecting the trap graft. Surface  
50 distances were largely reduced with the automatic methods. This is mostly due to the human  
51  
52

1 factor while manually aligning the donor and recipient. Moreover, there were some instances  
2 where the surface-based method resulted in statistically significant improvement over the  
3 volume-based counterpart. This result is inherent to the volume-based method that uses  
4 intensity values of images to perform the matching. The algorithm tends to be more affected  
5 by the high-intensity cortical bone than the remaining structures which might produce slight  
6 biases and misalignments. Furthermore, the image matching is done using the whole image  
7 volume where the high proportion of background voxels reduces the accuracy and increases  
8 computational time. In an actual clinical setup, the images would be cropped to cover only  
9 the volume of interest.

24 Moreover, our quantitative results showed a general trend where the surface-based approach  
25 results in the best quality of the overlap, whereas the manual method often comes last. The  
26 quality of surface overlap at the junctions between the donor and recipient is a major aspect  
27 that dictates the outcome of the surgery and the difficulty of the transplantation procedure.  
28 Furthermore, a smoother transition between the bones facilitates the placement of  
29 reconstruction plates and might have positive impact on the incorporation of the allograft into  
30 the host bed, thus might decrease the non-union rate. Registering a fragment to a whole pelvis  
31 will result in contact regions analogous to the junctions between the recipient and the  
32 allograft at the contact points.

65

66 Based on the obtained results, we can conclude that bone banking centres and allograft  
67 selection services could adopt the novel automatic methods. Among the direct advantages are  
68 improved quality of the selected donors and faster case processing and therefore reduced  
69 costs and higher throughput. The computational nature of the automatic methods can provide  
70 further benefits. For instance, they can be incorporated into the surgical planning pipeline to  
71

1 guide the clinician in extracting the graft and performing the resection, and to pre-operatively  
2 visualise the possible outcomes of the surgery. One could develop a fully or partially  
3 automatic system capable of managing the problem of allograft selection with features  
4 ranging from the collection of donor bones and archiving them to accurately planning the  
5 flow of the surgery. Moreover, the application of the automatic methods is not limited to the  
6 selection of allografts. With minor adaptation, they can be used for other surgical procedures  
7 such as bone augmentation using auto- or allografts. Bone augmentation is a common  
8 technique applied in several surgical specialties such as dentistry and craniomaxillofacial.<sup>22</sup>

22 Our evaluation was thorough in terms of the experimental setup and the clinical relevance of  
23 the criteria used in the analysis. However, further studies could include other anatomical  
24 regions where bone transplantation is commonly performed such as the proximal tibia or  
25 distal femur. Additionally, mechanical studies simulating the in-vivo performance of the  
26 grafts could be carried out in order to complement and further validate the design criteria  
27 presented in this and the original papers.

Figure 4: Three-dimensional view of a sample result of the surface registration method. The surface distance between the recipient and the donors from the databank is represented as color-coded surface maps. The leftmost sample is the best match, the middle one is the second best, whereas the rightmost bone is the one with the highest surface error metric.

Figure 8: Comparison of the post-registration (*left*) Hausdorff surface distance and (*right*) mean surface distance between the recipient and the candidate donors. FA, FB, and FC indicate the different fragments (\*:  $p < 0.05$ , \*\*:  $p < 0.01$ , \*\*\*:  $p < 0.001$ ).

**Table 1:** Agreement between the different methods on the choice of the best three candidate donors using Cohen’s kappa test.  $F_A$ ,  $F_B$ , and  $F_C$  indicate the different fragments.

| Agreement over best 3 |                |          |                |           |
|-----------------------|----------------|----------|----------------|-----------|
| Cohen’s kappa         |                |          |                |           |
| Fragment              | Methods        | $\kappa$ | CI             | Agreement |
| Whole                 | Volume/Manual  | 0.240    | 0.074 – 0.576  | Fair      |
|                       | Surface/Manual | 0.120    | -0.106 – 0.346 | Slight    |
|                       | Surface/Volume | 0.480    | 0.295 – 0.665  | Moderate  |
| $F_A$                 | Volume/Manual  | 0.325    | 0.074 – 0.576  | Fair      |
|                       | Surface/Manual | 0.044    | -0.246 – 0.333 | Slight    |
|                       | Surface/Volume | 0.480    | 0.295 – 0.665  | Moderate  |
| $F_B$                 | Volume/Manual  | 0.550    | 0.340 – 0.761  | Moderate  |
|                       | Surface/Manual | 0.494    | 0.272 – 0.716  | Moderate  |
|                       | Surface/Volume | 0.920    | 0.843 – 0.997  | Perfect   |
| $F_C$                 | Volume/Manual  | 0.381    | 0.139 – 0.624  | Fair      |
|                       | Surface/Manual | 0.325    | 0.074 – 0.576  | Fair      |
|                       | Surface/Volume | 0.440    | 0.249 – 0.631  | Moderate  |
